(Received 18 May 2015; published 30 July 2015)

We propose to experimentally explore the Haldane phase in spin-one XXZ antiferromagnetic chains using trapped ions. We show how to adiabatically prepare the ground states of the Haldane phase, demonstrate their robustness against sources of experimental noise, and propose ways to detect the Haldane ground states based on their excitation gap and exponentially decaying correlations, nonvanishing nonlocal string order, and doubly degenerate entanglement spectrum.

I. INTRODUCTION

In a quantum simulation experiment, the behavior of a complex quantum model is examined using a controllable system, which acts as the simulator [1–3]. Collections of trapped atomic ions have emerged as excellent standards for quantum simulations of interacting spin models. These electrically charged particles are confined in an electromagnetic trap, micrometers apart from one another [4,5]. Thanks to precise spin manipulation capabilities, near-perfect spin readout, and a variety of cooling [6,7] and dynamical decoupling techniques [8–16], trapped ions can be made to follow target Hamiltonians with high fidelity [17,18], making them one of the most promising candidates for quantum simulation.

To date, trapped ions have mostly been used to simulate spin-one-half Hamiltonians, showing the phase transition from the (anti)ferromagnetic to paramagnetic phases in the Ising model [19–29] and long-range correlation functions in the XX model [30,31]. By enlarging the spin’s degree and moving into integer spin chains, new and subtle physics can appear [32–40]; for example, the local orders vanish and we are left with hidden orders only [41].

In the last few decades considerable efforts have been made to investigate the nonlocal physics which appears in integer spin chains, e.g., a spin-one XXZ antiferromagnetic (AFM) Hamiltonian,

\[ H = \sum_{i,j} J_{i,j} (S_i^x S_j^x + S_i^y S_j^y + \lambda S_i^z S_j^z) + D \sum_i (S_i^z)^2. \]  

(1)

In 1983, Haldane conjectured [34] that Heisenberg chains of integer spins with nearest neighbors antiferromagnetic interactions are gapped, unlike the gapless half-integer spin chains. This energy gap corresponds to short-range exponentially decaying correlation functions, compared to the long-range power law decaying correlations of half-integer spin systems. Later, Den Nijs and Rommelse [35] suggested that the Haldane phase of the spin-one chain is governed by a hidden order, which can be characterized by a nonlocal string order parameter. It is consistent with a full breaking of a hidden \(Z_2 \times Z_2\) symmetry, which was revealed using a nonlocal unitary transformation by Kennedy and Tasaki [36,37]. In 2010 Pollmann et al. [38] showed that the Haldane phase can also be described by the doubly degenerate entanglement spectrum. These characteristics hint that the Haldane phase is a topologically protected phase in one dimension. Hence, quantum simulation of the Haldane phase enables the exploration of topological behavior in relatively simple systems.

Recently an experiment by Senko et al. [39] has used trapped ions to simulate spins in higher degrees. In this experiment a spin-one Hamiltonian was engineered using state-dependent laser forces, paving the way toward highly controllable quantum simulation experiments that exhibit hidden orders. Previously, we proposed how to engineer the Hamiltonian of Eq. (1) using microwave-based forces on the trapped-ion spins [40]. In this previous derivation of the Hamiltonian, we could cover only \(0 \leq \lambda \leq 2\) of the phase diagram (Fig. 1). A natural way to extrapolate the microwave approach to a laser-based implementation is to use non-co-propagating Raman beams instead of a magnetic field gradient [42] to induce the spin-phonon coupling.

In this paper, we first propose an approach to achieving the same result as in [40], but with a laser-based implementation. Then, we propose a new approach for quantum engineering, Eq. (1), while covering the whole positive \(\lambda \geq 0\) plane of the phase diagram (Fig. 1). Instead of having the XX (flip-flop) Hamiltonian \(S_i^x S_j^x + S_i^y S_j^y\) as our starting point, in the new approach we engineer a Mølmer-Sørensen (MS)-like gate [43] for spin-one systems that takes the form of an Ising Hamiltonian \(S_i^x S_j^x\).

We have found three ways to implement the MS gate for spin-one systems [43–45]. These schemes were originally proposed for two-level systems (qubits), but can be extrapolated to three-level systems (qutrits). For simplicity, we consider the first and second approaches for laser-based designs, although a similar derivation exists for the third one, and also for microwave-based implementations.

We explain how to move experimentally to the interaction picture: namely, how to measure in the appropriate basis. Furthermore, we give a detailed explanation of the adiabatic path for reaching the Haldane phase. We stress that our model is robust to the main noise sources in experiments, exploiting dressing fields as a dynamical decoupling technique, and operating in a decoherence free subspace, enabling longer adiabatic evolution times.
II. MODEL

The phonons. In our model we have \( N \) trapped ions each of mass \( m \) and electric charge \( e \), forming a linear chain along the z axis, \( r_n^0 \). The ion formation is determined according to the equilibrium of the Coulomb repulsion between the ions, and the trapping forces. The vibrations of the ions around their settled points, \( \Delta r_{i\alpha} \), are solved in the harmonic approximation obtaining the normal modes \( M_{i\alpha}^a \) and \( v_n^a \), which are the eigenstates and the eigenvalues of the \( n^\text{th} \) mode and the \( i^\text{th} \) ion in the \( \alpha \) direction, respectively. Thus, the ion displacements are represented as \( \Delta r_{i\alpha} = \sum_n M_{i\alpha}^a \sqrt{\hbar / 2m v_n^a} (b_{i\alpha} + b_{i\alpha}^\dagger) \), and the vibration Hamiltonian is represented as \( H_{\text{vib}} = \sum_{n\alpha} v_n^b b_{n\alpha}^{\dagger} b_{n\alpha} \), where \( b_{n\alpha}^{\dagger}, b_{n\alpha} \) are the creation and annihilation of a phonon, respectively [46–48].

The spin. The second quantum degree of freedom in this model is the spin. For our derivation, we consider the hyperfine structure of the \( ^{171}\text{Yb}^+ \) ion (Fig. 2), with microwave energy separation between the singlet and the three triplet states [49,50]. Removing the \( m_F = 0 \) state (\( |0\rangle \)) from the triplet, we are left with three energy levels for modeling the simulated spin-one system. Quantum manipulation can occur using Raman transitions via virtual excited states, or using microwave driving fields. Note that any other ion having three different energy states in the microwave regime would suffice for modeling the spin-one particle, as long as there is a virtual excited state, through which the Raman transitions between the three levels can occur [51].

The interaction. In trapped-ion systems, the spin-spin interaction takes place by exchanging a virtual phonon between the different ions; therefore, a spin-phonon coupling term is needed. Using laser Raman beams, the spin-phonon coupling term is achieved by a sufficiently large Lamb-Dicke parameter of the non-co-propagating beams [51]. For antiferromagnetic interactions, we typically choose a radial vibration mode as the mediator between the spins [52,53]. Therefore, three counterpropagating Raman beams having a momentum difference along the radial direction perform the two beat frequencies corresponding to the \( \delta \) detuned transitions between \( | -1 \rangle \rightarrow |0\rangle \) and \( | 1 \rangle \rightarrow |0\rangle \), with a \( \pi \) phase difference (Fig. 2). In the interaction picture with respect to the radial vibration Hamiltonian and the bare state energy structure, we obtain the red sideband transition for a three-level system:

\[
H_{\text{red}} = \sum_{n,j} \frac{i \Omega_{j,n}}{2\sqrt{2}} (F_j^+ e^{i\delta t} - \text{H.c.})(b_j^\dagger e^{i\nu_n t} + \text{H.c.}).
\]

After applying the Lamb-Dicke approximation \( \eta_{j,n} \sqrt{N_n + 1} \ll 1 \), where \( N_n \) is the average number of phonons of the \( n^\text{th} \) mode, \( \eta_{j,n} = k L M_{j,n} \sqrt{\hbar / 2m v_n} \) is the Lamb-Dicke parameter, \( k_L \) is the laser's wave number, and \( F_j^\pm = \sqrt{2}(1)^\pm |0\rangle + |0\rangle ^\pm (-1) \). In the second-order perturbation approach [54], this results in an XX Hamiltonian in addition to a residual term [39]:

\[
H_{XX} = \sum_{i \leq j} J_{ij}^\text{eff} \left( (F_i^+ F_j^+ + F_j^+ F_i^+) (1 - \delta_{i,j}) - \frac{(F_i^2)^2}{2} \delta_{i,j} \right),
\]

\[
H_{\text{res}} = \sum_{j,n,m} J_{j,n,m}^\text{res} F_j^+ \left( b_j^\dagger b_m + \frac{1}{2} \delta_{n,m} \right) e^{-i(\nu_n - \nu_m)t},
\]

where

\[
J_{ij}^\text{eff} = \sum_n \frac{\eta_{i,n} \eta_{j,n}}{2} \frac{\nu_n \Omega^2}{\delta^2 - \nu_n^2} \propto |\tilde{r}_i^0 - \tilde{r}_j^0|^{-\xi},
\]

\[
J_{j,n,m}^\text{res} = \Omega^2 \delta \frac{\eta_{j,n} \eta_{j,m}}{4} \left( \frac{1}{\delta^2 - \nu_n^2} + \frac{1}{\delta^2 - \nu_m^2} \right).
\]

Our model can be decoupled from the residual term if \( J_{j,n,m}^\text{res} \) is approximately uniform across the chain, such that \( H_{\text{res}} \propto \sum_j F_j^2 \). This is due to the fact that the model's relevant ground states, as we will see later in this paper, have a vanishing projection over the z axis, thus the experiment is performed in the decoherence-free subspace. As was suggested in Ref. [39], this residual term can be eliminated,
We also assume that
\[
\frac{\Omega \Omega_D}{8\sqrt{2}} \left( \frac{1}{\Delta_D} + \frac{1}{\delta} \right) \ll \Delta_D - \delta,
\]
\[
\frac{\Omega \Omega_D}{8\sqrt{2}} \left( \frac{1}{\delta} + \frac{1}{\delta - \nu_n} \right) \ll \Delta_D - (\delta - \nu_n), \tag{6}
\]
such that every undesired Raman-like coupling between the \(\Delta_D\) detuned transition and the carrier or sideband transitions of the counterpropagating Raman beams are suppressed.

Generating a tunable \(D\) term can alternatively be achieved by regarding the \(|0\rangle\) bare state energy level as \(D'\) shifted, corresponding to its real value in the hyperfine structure [Fig. 3(b)]. In other words, we impose \(D'\) detuning on all the driving fields generating the \(XX\) Hamiltonian [Eq. (3)]. Therefore, we are left with the term \(D'\)\(|0\rangle\)\(|0\rangle\) \(D'\) \(F_0^2\). In order to tune this term we have to shift all the driving field transitions continuously, as was recently demonstrated in [39].

Note that the anisotropy \(D\) term is slightly different from these \(D'\) terms, since the model is \(\theta\) rotated while generating the \(\lambda\) term, as is explained below.

**Generation of the Ising-like \(\lambda\) term.** The Ising-like anisotropy term \(\lambda J_{i,j} F_i^z F_j^z\) is produced using a technique, which is revealed by considering the interaction picture. It is done by adding a spin operator term, \(\theta\) rotated from the \(z\) axis, namely, \(\Omega F_{z,\theta} = \Omega (F_z \cos \theta + F_\alpha \sin \theta)\), where \(\alpha\) can be either \(x\) or \(y\) or their superposition (XY plane), and generating each component separately. \(\Omega F_z \cos \theta\) can be produced similarly to the two ways that the \(D\) term was generated. The first way is to drive the transitions between \(|\pm 1\rangle \leftrightarrow |0\rangle\) with \(\pm \Delta_c\) detunings, respectively. These transitions can be generated using co-propagating Raman beams, or alternatively using microwave driving fields, with a Rabi frequency \(\Omega_c\), such that the effective ac Stark shifts result in the \(\Omega F_z \cos \theta\) term, with \(\Omega^2 \cos \theta = \Omega_c^2 / \Delta_c\) [Fig. 4(a)], under the assumption \(\Omega_c \ll \Delta_c\). Similarly to the \(D\) generating case [Eq. (6)], we have to keep \(\Delta_c\) far detuned from all the other detunings, such that every undesired Raman-like transition, coming from coupling between this term to the \(D\) generating transitions or the counterpropagating Raman beams, will be suppressed. The second way to induce \(\Omega F_z \cos \theta\) is by imposing detunings on the non-co-propagating Raman beams, i.e., by imposing \(\pm \Omega_c \cos \theta\) detunings on the transitions between \(|\pm 1\rangle \leftrightarrow |0\rangle\), respectively, such that the \(F_z \cos \theta\) term is set aside from the bare state energy structure [Fig. 4(b)].

The second term \(\Omega F_{z,\theta} \sin \theta\) is obtained using the carrier transitions, where their relative phase difference determines the resulting operator direction \(\alpha\). The carrier transitions can be applied either using co-propagating laser Raman beams, or simply using microwave driving fields, with a Rabi frequency \(\Omega_{\text{car}} = \Omega' \sin \theta \sqrt{2}\) [Fig. 5(a)].

By applying a \(\theta\) rotation around the perpendicular axis, such that \(F_{z,\theta}\) is transformed into \(F_\alpha\), the new spin operators and the new basis are \(\theta\) rotated as well. If we move to the interaction picture with respect to the new term we have built \(\Omega F_{\alpha}\), and use the RWA where we require \(\frac{\Omega_c^2 \nu_n^2}{\delta - \nu_n} \ll \Omega' \ll \delta - \nu_n\), we
end up with the following effective Hamiltonian:

\[
H_{\text{eff}} = \sum_{i<j} J_{ij}^{\text{eff}} \left( \frac{(F_i^+ F_j^+ + F_j F_i^+)}{2} \cos^2 \theta - \frac{\sin^2 \theta}{2} \right) + \sum_i \left( D' - \frac{J_{ii}^{\text{eff}}}{2} \right) \left( \cos^2 \theta / 2 - \sin^2 \theta \right) (F_i^+)^2. \tag{7}
\]

We have obtained the required spin-one XXZ AFM Hamiltonian, where we can only cover 0 \( \leq \lambda \leq 2 \). Experimentally, the following parameters are realistic: \( v_n = 2\pi \times 5 \text{ MHz} \), \( \delta = 2\pi \times 5.1 \text{ MHz} \), \( \Omega = 2\pi \times 500 \text{ kHz} \), and \( \Omega' = 2\pi \times 10 \text{ kHz} \), which give \( J_{ii}^{\text{eff}} \approx 2\pi \times 1 \text{ kHz} \), such that 0 < \( D' < 2\pi \times 10 \text{ kHz} \).

An important advantage over the previous derivation in [40], is that in order to obtain the antiferromagnetic interactions, \( \delta \) should be larger than the secular frequencies of the radial vibrational modes, rather than the Rabi frequency \( \Omega / \sqrt{2} \). Since one of the main experimental challenges is to reach a high Rabi frequency, in the present derivation we overcome this technical obstacle. As for the residual terms we dropped on the way, such as the carrier transition that yields a four-photon ac Stark shift and was neglected from Eq. (2), and the neglected fast rotating terms and the residual from Eq. (3), these terms operate with \( \sum_i F_i^+ \). Since the model’s relevant ground states have a vanishing projection over the \( z \) axis, we are decoupled from these undesired terms.

In this scheme, we move more than once to different interaction pictures. In the following section, we explain how this can be done experimentally.

III. MOVING TO THE INTERACTION PICTURE EXPERIMENTALLY

Since the measurement is taken in the laboratory frame and the effective Hamiltonian is derived after moving to several interaction pictures, we now show how the dynamics of the state in the laboratory frame relates to the dynamics determined by the last interaction picture. For this purpose, we take the general case where in the laboratory frame the evolution of the Schrödinger state is described as follows:

\[
H_i(t) = H_0 + H_{\text{int}}(t),
\]

\[
|\Psi_i(t)\rangle = U_i(t)|\Psi_i(0)\rangle, \tag{8}
\]

where \( t \) is the time ordering operator. Moving to the interaction picture, the dynamics is described as

\[
U^i_h(t) = \exp(i H_0 t),
\]

\[
H_{ih}(t) = U^i_h(t) H_{\text{int}}(t) U^i_h(0),
\]

\[
|\Psi_{ih}(t)\rangle = U_{ih}(t)|\Psi_{ih}(0)\rangle. \tag{9}
\]

Usually, the first interaction picture \( H_0 \) is time independent since it is the bare state energy structure. However, in general, \( H_0 \) can also be time dependent, where \( U^i_h(t) = \exp(i \int_0^t H_0(t')dt') \). Here, we only assume that \( H_0 \) is a single-particle operator or a global rotation, i.e., it does not create entanglement. In fact, if the realization of the \( D \) control parameter is achieved using detunings, varying it during the Haldane phase simulation experiment effectively results in having the first interaction picture \( H_0(t) \) time dependent.

Using the definition of the interaction picture,

\[
|\Psi_{ih}(t)\rangle = U^i_h(t)|\Psi_i(t)\rangle, \tag{10}
\]
we obtain the relation between the interaction and the Schrodinger pictures,

$$U_{1N}(t) = U_{1}^{\dagger}(t)U_{b}(t),$$  \hspace{1cm} (11)

since $|\Psi_{b}(0)\rangle = |\Psi_{1}(0)\rangle$.

Suppose that the first interaction frame is by itself a “Schrödinger” frame for the next interaction picture, such that

$$H_{b}(t) = H_{I}(t) + H_{int}^{\text{int}}(t),$$  \hspace{1cm} (12)

where $H_{I}(t)$ is a single-particle operator in the first interaction frame. As before,

$$U_{I}(t) = \exp \left( i \int_{0}^{t} H_{I}(t') dt' \right),$$

$$H_{b}(t) = U_{I}^{\dagger}(t)H_{b}(t)U_{I}(t),$$

$$|\Psi_{I}(t)\rangle = U_{I}(t)|\Psi_{1}(0)\rangle,$$  \hspace{1cm} (13)

thus,

$$U_{I}(t) = U_{1}^{\dagger}(t)U_{b}(t).$$  \hspace{1cm} (14)

Substituting Eq. (11) in Eq. (14) we obtain

$$U_{J}(t) = U_{0}(t)U_{1}(t)U_{I}(t); \quad |\Psi_{J}(t)\rangle = U_{0}(t)U_{1}(t)|\Psi_{I}(t)\rangle.$$  \hspace{1cm} (15)

For $N + 1$ interaction pictures in our derivation, we obtain

$$U_{J}(t) = U_{0}(t)U_{1}(t)\cdots U_{N}(t)U_{b}(t),$$

$$|\Psi_{J}(t)\rangle = U_{0}(t)U_{1}(t)\cdots U_{N}(t)|\Psi_{b}(t)\rangle.$$  \hspace{1cm} (16)

In order to move experimentally to the interaction picture, such that the Schrödinger state will evolve according to the last interaction Hamiltonian, we have to rotate the system back to counter $U_{0}(t)U_{1}(t)\cdots U_{N}(t)$. There are two main ways to move experimentally to the interaction picture, as will be discussed next.

The first and straightforward way is by applying $N$ concatenated global rotations for each interaction picture, except for the first one. Suppose we want to measure the system after time $t$, in which all the driving fields were on. In order to counter the last interaction unitary $U_{N}(t)$, we only block the driving fields that generate the simulated Hamiltonian $U_{b}(t)$, while operating with all the driving fields that are responsible for the interaction pictures. This will be done for time $t_{N}$, such that we obtain

$$U_{I}(t + t_{N}) = U_{0}(t + t_{N})U_{1}(t + t_{N})\cdots U_{N}(t + t_{N})U_{b}(t + t_{N}),$$  \hspace{1cm} (17)

and $t_{N}$ is determined by $U_{N}(t + t_{N}) = \mathbb{I}$. The same approach can be used to counter all the other interaction unitary, obtaining the following pulse sequence. $\S 1$.) All the driving fields for the experiment time $t$. $\S 2$.) All the driving fields that are responsible for the $H_{I}(t)$ to $H_{N}(t)$ interaction pictures for $t_{N}$ time. $\S 3$.) All the driving fields that are responsible for the $H_{1}(t)$ to $H_{N-1}(t)$ interaction pictures for $t_{N-1}$ time.

$\S N$.) Only the driving fields that are responsible for the $H_{1}(t)$ interaction pictures for $t_{1}$ time.

In that way, we obtain the following relation between the last interaction picture and the Schrödinger one:

$$U_{I}(t + t_{N} + \cdots + t_{1}) = U_{0}(t + t_{N} + \cdots + t_{1})U_{1}(t + t_{N} + \cdots + t_{1})\cdots U_{N}(t + t_{N})U_{b}(t).$$  \hspace{1cm} (18)

Setting $U_{b}(t + t_{N} + \cdots + t_{1}) = \mathbb{I}$ for all $1 \leq k \leq N$, the Schrödinger state therefore evolves according to the last interaction picture,

$$U_{J}(t + t_{N} + \cdots + t_{1}) = U_{0}(t + t_{N} + \cdots + t_{1})U_{I}(t),$$  \hspace{1cm} (19)

with an additional phase $U_{0}(t + t_{N} + \cdots + t_{1})$, which we do not measure. If we want to measure in any different basis, we can rotate the system using any one of $U_{b}(t + t_{N} + \cdots + t_{1}) = e^{i\alpha_{b}t_{N}}$.

The second way to move experimentally to the interaction picture is simpler. Since the prefactor of $U_{I}(t)$ is a global rotation $U_{0}(t)U_{I}(t)\cdots U_{N}(t) = e^{i\alpha_{b}t_{N}}$, we can apply just one global rotation to counter the total interaction unitary rotations all together. Since any rotation in the Bloch sphere can be generated by two independent rotations (e.g., two orthogonal rotations), it is sufficient to use the first and second interaction pictures, namely $H_{0}(t)$ and $H_{I}(t)$, which are orthogonal rotations for that task. Measuring in any other basis can be achieved by an additional rotation, which can be added to all the interaction unitary, and thus be represented effectively with $H_{0}(t)$ and $H_{I}(t)$. Next, we explicitly show how to apply the first approach in the two derivations of the XXZ-D Hamiltonian.

Experimental realization. While generating the XXZ-D Hamiltonian we move twice to different interaction pictures: The first one is with respect to the bare energy gap of the qutrit, yielding the following interaction unitary:

$$U_{0}(t) = \exp(-i[(\omega_{0} - D')|0\rangle\langle 0| + \lambda_{1}|1\rangle\langle 1| - \lambda_{1}|0\rangle\langle 0| + |1\rangle\langle 1| - |0\rangle\langle 0|]t),$$  \hspace{1cm} (20)

where we used the detuning approach to generate the $D$ term. The second interaction picture is with respect to the $\lambda$-generating term, resulting in the following interaction unitary:

$$U_{1}(t) = \exp(-i\Omega'\cos \theta F_{z} + \sin \theta F_{z} t),$$  \hspace{1cm} (21)

with $\alpha = x, y$. Moving to these interaction pictures results in the effective Hamiltonian [Eq. (7)] which yields the simulated evolution $U_{I}(t)$.

As was discussed above, in order to move to the interaction frame, we first have to shut down the effective Hamiltonian. This is done by blocking the two non-co-propagating Raman beams (setting $\Omega = 0$), and eliminating the $D'$ term. Shutting down the effective Hamiltonian should take $t_{I}$ such that $U_{I}(t + t_{I}) = \mathbb{I}$.

There is no need to counter $U_{0}$ since it only yields an unmeasured phase. Leaving the experiment at this point results in measuring the state in the $F_{z}$ basis. Now, if we want to measure in the simulated basis, namely $F_{z} = \cos \theta F_{z} + \sin \theta F_{z}$ for $\alpha = x, y$, we need to rotate the system around a perpendicular axis. Since by using the carrier transitions we generate $\Omega' \sin \theta F_{z}$, we have to rotate the system with an $F_{\beta}$
operation, with $\beta \perp \alpha$. This can be achieved after counteracting $U_1$, by a $\pi/2$ phase change of the laser or microwave driving field, such that instead of operating with $F_z$, the driving field will operate with $F_y$. In a similar way we can measure in any basis we choose.

**IV. ADIABATIC QUANTUM SIMULATION**

Once we know how to quantum engineer the Hamiltonian of the system under investigation with tunable parameters, the adiabatic quantum simulation proceeds as explained below. We initialize the system in a trivial phase by appropriately setting the parameters of the Hamiltonian, and we initialize the system’s state in its trivial ground state. Then, we change the Hamiltonian parameters adiabatically, slower than the energy gap, such that the system stays in the ground state of the instantaneous Hamiltonian, until it reaches the ground state of the nontrivial phase that we want to investigate.

In our case the system under investigation is the antiferromagnetic XXZ-D spin-1 Hamiltonian, and its trivial phase is the large-$D$ phase, with a tensor product of $|0\rangle$ in each site, as its trivial ground state. Since we are operating with a rotated basis $F_z = \cos \theta F_z + \sin \theta F_y$, we can initialize the system in a tensor product of $|0\rangle$ in the $F_z$ basis using polarization. Then we can rotate the state with orthogonal operations: $F_\beta$ (with $\alpha \perp \beta$), similarly to what was described above. Now, we set a large-$D$ parameter of the Hamiltonian, and start the adiabatic variation of the $D$ parameter until we reach the Haldane phase regime.

When getting closer to the thermodynamic limit, the energy gap in the second-order phase transition closes; thus the adiabatic approximation cannot hold for increasingly long chains. Overcoming this problem takes advantage of the fact that the Haldane phase is a symmetry-protected topological phase. Thus, we can use a symmetry-breaking perturbation in order to go around the $D \rightarrow H$ phase transition, while still operating adiabatically (Fig. 6).

The Haldane phase is protected by the following symmetries: a bond centered spatial inversion $\tilde{S}_j \rightarrow \tilde{S}_{-j+1}$, a time reversal symmetry $\tilde{S}_j \rightarrow -\tilde{S}_j$ and the dihedral $D_2$ symmetry, which is a $\pi$ rotation around the $x$, $y$, and $z$ axes. In order to break all these symmetries we add a perturbation term $H_{\text{pert}} = -\hbar \sum_i (-1)^i S_z^i$. Since we know how to engineer the $S_z$ term, which is $S_z$, in our derivation, the symmetry breaking term can be produced by individual addressing, which is achieved by focusing the laser beams.

Note that since the quantum simulation experiment is adiabatic, its duration has a lower bound determined by the energy gap. However, like any other quantum experiment, it also has an upper bound that is determined by the coherence time. If the experiment lasts longer than the coherence time, decoherence processes might destroy the quantum information carried by the system, and the results cannot be trusted. Hence, immunity to the main noise sources is crucial.

**V. ROBUSTNESS OF THE GROUND STATES TO NOISE**

To benefit from a long coherence time we need to be decoupled from the main noise sources. The most fidelity damaging noise source is the ambient magnetic field. Usually, to simulate spin-1/2 systems, the $^{171}$Yb$^+$ clock states are used. However, when simulating spin-1, the use of the Zeeman levels leaves the system vulnerable to magnetic field fluctuations. The second most important noise source is the fluctuations of the Rabi frequencies of the non-co-propagating Raman beams that generate the spin-spin interaction $\Omega$, the carrier transition $\Omega_{\text{car}}$, and the driving fields that generate $\Omega'$. Specifically, these driving fields operate as dressing fields performing dynamical decoupling, thus, we are left with noise sources in the $z$ direction. However, since the relevant ground states of the large $D$ and the Haldane phases belong to the decoherence free subspace, we are protected against these noise terms.

The ground state of the large $D$ phase is the topologically trivial state of a tensor product of $|0\rangle$, and the ground state of the Haldane phase has the same number of sites occupied by $|\uparrow\rangle$ and $|\downarrow\rangle$, where $|\uparrow\rangle$ and $|\downarrow\rangle$ are the eigenstates of $S_z^i$ with eigenvalues $1$, $-1$, respectively. Therefore, these ground states are eigenstates of $\sum_i F_z^i$, with a zero eigenvalue, such that our model is decoupled from this operation and thus from these noise sources. Thus, the quantum simulation operates in the decoherence free subspace. For the same reason, all the neglected ac Stark shifts resulting in $\sum_j F_j^j$ could have been dropped in the derivation.

**VI. VERIFICATION OF THE HALDANE PHASE’S GROUND STATE**

The ground states of the Haldane phase are characterized by (1) an excitation gap and exponentially decaying correlations of the local order $C_{\text{str}}^\sigma(i-j) = \langle S_{\alpha}^i S_{\beta}^j \rangle$, where $\langle \rangle$ denotes the expectation value in the ground state, (2) a nonvanishing non-local string order $O_{\text{str}}^\alpha(H) = \lim_{|i-j| \rightarrow \infty} C_{\alpha}^\sigma(i-j)$, where
with the like in the derivation of the previous paper \cite{40}. This has to
used to generate $\Omega_1$ proposal \cite{44}. Here, we use the carrier transitions that were
addition to the red sideband ones, based on Ref. \cite{43}. Yet, beat frequencies to drive the blue sideband transitions in
way to generate the MS transitions is by applying additional
interaction term instead of the $XX$ term; namely, we have to perform a MS-like gate of spin-
\[ \alpha \]

This looks like we are not proceeding with the derivation of Eq. (1), but rather are going backwards. We have already had the XX Hamiltonian [Eq. (3)], and with additional effort \cite{22}, we only obtain the Ising Hamiltonian. However, using the trick for generating the $\lambda$-like term, we also generate the XXZ Hamiltonian, this time covering the whole positive $\lambda$ phase diagram, unlike the previous derivation. In the following, we pursue a tunable $D$ term, and a tunable $\lambda$ term.

Generation of the control anisotropy $D$ term. As before, generating the tunable $D$ term can be done in two ways: generating an ac Stark shift, or imposing detunings. To generate the detuned transitions to implement the first method we can apply an additional $\Delta_D$ detuned microwave driving field, corresponding to the transition between the two zero states of the triplet and the singlet, $|0\rangle \leftrightarrow |\Omega\rangle$. In a similar way, we can obtain the same result by applying co-propagating Raman beams corresponding to the same transition \cite{3a}. We then follow the previous steps of derivation: By first transforming to the dressed state basis, where $|0\rangle \rightarrow (|u\rangle - |d\rangle)/\sqrt{2}$, and then moving to the rotating frame of $\Delta_D$, $\frac{\Omega_D}{\sqrt{2}}$, we obtain
\[ \frac{\Omega_D}{\sqrt{2}}|u\rangle \langle \Omega| e^{i\Delta_D \cdot \frac{\Omega_D}{\sqrt{2}} \frac{\Omega_D}{\sqrt{2}}} - |d\rangle \langle 0| e^{i\Delta_D \cdot \frac{\Omega_D}{\sqrt{2}} \frac{\Omega_D}{\sqrt{2}}} + \text{H.c.} \].

In the second perturbation theory, assuming $\frac{\Omega_D}{\sqrt{2}}, \frac{\Omega_D}{\sqrt{2}} \ll \Delta_D$, and $\frac{\Omega_D}{\sqrt{2}} \ll \sqrt{2} \Omega\text{car}$, only the ac Stark shifts survive, whereas the other off-diagonal terms coming from the Raman transitions between $|u\rangle \leftrightarrow |d\rangle$ are suppressed in the RWA. Thus, we are left with the desired $D(S_y)^2$ term, setting $D' = \frac{\Omega_D}{\sqrt{2}}$. Generating a tunable $D$ term can alternatively be achieved by regarding the $|0\rangle$ bare state energy level as $2D'$ shifted corresponding to its real value in the hyperfine structure \cite{3b}. That is to say, we impose $2D'$ detuning on all
there are two ways to realize this term of the $\lambda$-generating trick: (1) (a) to engineer $\Omega S_\alpha \sin \theta$, we apply additional co-propagating laser Raman beams, which perform the two Raman transitions between $|\mp 1\rangle \leftrightarrow |0\rangle$ with $\pm \delta_{\alpha} = \pm \left( \frac{\Omega_F}{\Delta} - \Omega' \cos \theta \right) \text{detunings}$, $\pm \frac{\pi}{2}$ initial phases, and the same effective Rabi frequency $\Omega_{\alpha} = \sqrt{2} \Omega' \sin \theta$, respectively; (2) (b) to engineer $-\Omega' \cos \theta S_\alpha$, we apply a $\pm$-polarized radio-wave driving field, on resonance with the dressed-state energy structure [Fig. 5 (b)], and with a Rabi frequency of $\Omega_{\alpha} = 2 \Omega' \sin \theta$. Regardless of method, we obtain the desired term by moving to the rotating frame of the dressed energy structure, and using RWA while assuming $\Omega' \ll \sqrt{2} \Omega$.

We move to the interaction picture with respect to the new term we have built $\Omega \Sigma$ and use the RWA where we require $\frac{(\Omega_{\alpha} \delta - \nu_n)^2}{\hbar^2} \ll \Omega' \ll \delta - \nu_n$, we end up with the following effective Hamiltonian:

$$H_{\text{eff}} = \sum_{i < j} J_{ij}^{\text{eff}} \left[ \frac{1}{2} \left( \left( S^x_i S^x_j + S^y_i S^y_j \right) \frac{\cos^2 \theta}{2} + S^z_i S^z_j \sin^2 \theta \right) + \sum_{j} \left( D' - J_{ii}^{\text{eff}} \right) \left( \frac{\cos^2 \theta}{2} - \sin^2 \theta \right) (S^z_j)^2 \right].$$

Therefore, we have obtained the required spin-one XXZ AFM Hamiltonian, while covering the whole positive $\lambda \geq 0$ plane in the phase diagram. Experimentally, the following parameters are realistic: $\nu_j = 2\pi \times 5$ MHz, $\delta = 2\pi \times 5.1$ MHz, $\Omega_{\text{car}} = 2\pi \times 1$ MHz, $\Omega' = 2\pi \times 10$ kHz, $\Omega = 2\pi \times 500$ kHz, $\eta_n, \eta_j = 0.14$, which give $J_{ii}^{\text{eff}} = 2\pi \times 1$ kHz, such that $0 < D < 2\pi \times 10$ kHz.

### VIII. EXPERIMENTAL REALIZATION OF MOVING TO THE INTERACTION PICTURE

In this scheme of generating the XXZD Hamiltonian, we move to three interaction pictures: The first one is with respect to the bare energy gap of the qudit, which yields the same first interaction unitary $U_0(\tau)$ [Eq. (20)] of the first approach. The second interaction picture is with respect to the microwave dressed state energy gap, giving rise to the following interaction unitary:

$$U_1(\tau) = \exp \left( -i \left[ \frac{\Omega_{\text{car}}}{\sqrt{2}} - \Omega' \cos \theta \right] \sum F^i_\alpha \tau \right),$$

and the last interaction picture is with respect to a superposition of the $\theta$-rotated term used for generating the $\lambda$-generating trick. It results in the following interaction unitary:

$$U_2(\tau) = \exp( -i \Omega [\cos \theta F_z + \sin \theta F_y] \tau ),$$

with $\alpha = z, y$. Moving to these interaction pictures results in the effective Hamiltonian [Eq. (27)], which yields the simulated evolution $U_{12}(\tau)$.

As was discussed above, in order to move to the interaction frame, we first have to shut down the effective Hamiltonian. This is done by blocking the two non-co-propagating Raman beams (setting $\Omega = 0$), and eliminating the $D'$ term for $t_2$ time duration, such that $U_{2}(\tau + t_2) = \mathbb{I}$.

The next stage is counterwing $U_1$. For that purpose, we have to shut down the driving fields responsible for $U_2$. Specifically we have to block the driving fields that generate $\Omega' \sin \theta F_\alpha$, and to change the Rabi frequency of the carrier transitions to $\Omega_{\text{car}}/\sqrt{2} - \Omega' \cos \theta$. This stage should take $t_1$, such that $U_1(\tau + t_2 + t_1) = \mathbb{I}$. As before, there is no need to counter $U_0$, and we can measure in any basis we desire.

Similarly to the above scheme, during the adiabatic quantum simulation experiment, we counter the main noise sources—the ambient magnetic field fluctuations, and the Rabi frequency fluctuations—using a combination of the continuous dynamical decoupling technique with decoherence-free subspace.

IX. SUMMARY

We have discussed how to quantum engineer the spin-one XXZ-D AFM Hamiltonian with two schemes. The first covers $0 \leq \lambda \leq 2$, whereas the second covers the whole positive $\lambda \geq 0$ plane in the phase diagram. It enables us to explore the regime of the Heisenberg Hamiltonian of integer spin systems where the Haldane phase resides. We have explained how to adiabatically generate this nontrivial topological phase, starting from the large $D$ phase with its trivial ground state. During the adiabatic path, the ground states are robust to the fluctuations in the magnetic field and Rabi frequencies, and belong to a decoherence free subspace. This permits a longer adiabatic path with higher fidelities. We have also shown how the Haldane phase can be verified with simple experimental measurements. This proposal may thus constitute an important step towards exploring topological phases with trapped ions.

[59] We can measure the order correlations with three measurements: $P_{1,1}^{i,j}, P_{-1,-1}^{i,j}$, and $P_{0}^{i,j}$, where the latter is the probability to measure at least one of the ions ($i$ or $j$) in the $|0\rangle$ state. This uses the fact that $P_{1,1}^{i,j} + P_{-1,-1}^{i,j} = 1 - P_{0}^{i,j}$.
